

Lecture 12: Maximum likelihood (continued)

χ^2 fitting procedure!

Midterm tools reviewed

from Lecture 10: Maximum Likelihood discussion

Nonlinear fits are often easy in MATLAB (or other high-level languages) if you can make a reasonable starting guess for the parameters:

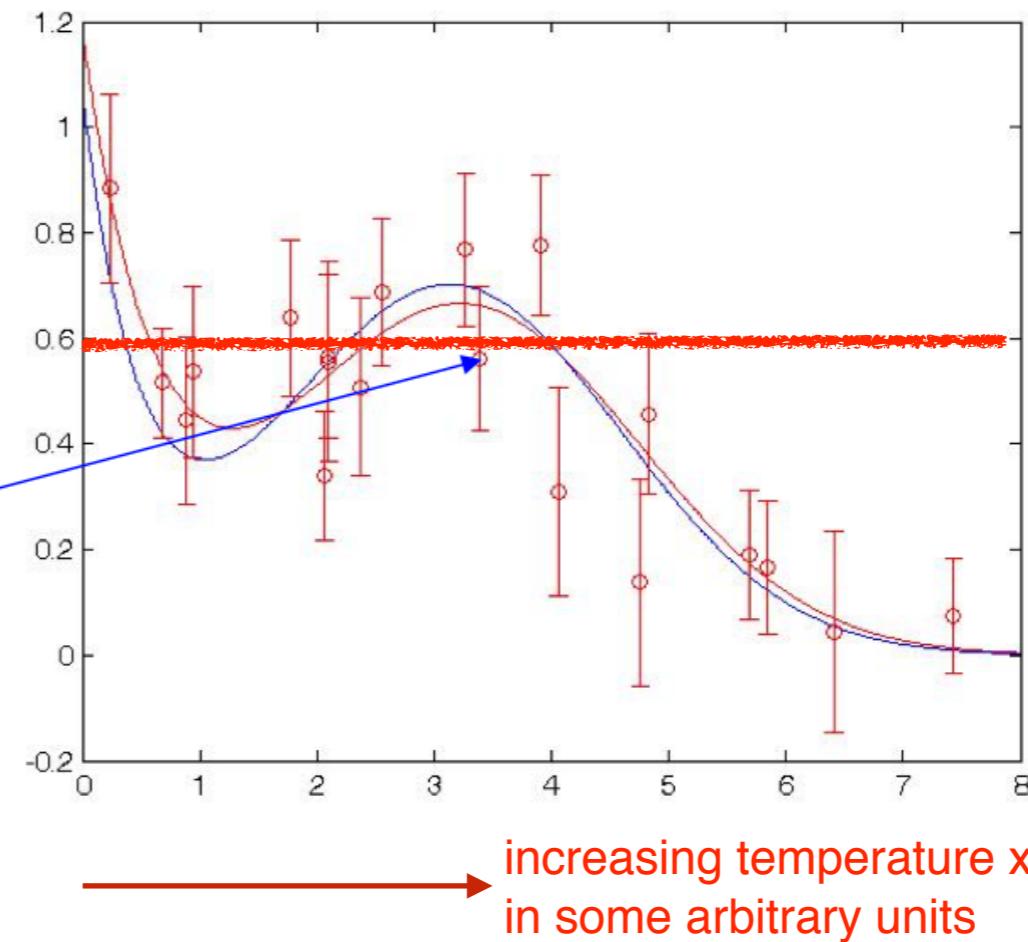

$$y(x|\mathbf{b}) = b_1 \exp(-b_2 x) + b_3 \exp\left(-\frac{1}{2} \frac{(x - b_4)^2}{b_5^2}\right)$$
$$\chi^2 = \sum_i \left(\frac{y_i - y(x_i|\mathbf{b})}{\sigma_i} \right)^2$$

```
ymodel = @(x,b) b(1)*exp(-b(2)*x)+b(3)*exp(-(1/2)*((x-b(4))/b(5)).^2)
chisqfun = @(b) sum(((ymodel(x,b)-y) ./sigma).^2)
```

```
bguess = [1 2 .5 3 1.5]
bfit = fminsearch(chisqfun,bguess)
xfit = (0:0.01:8);
yfit = ymodel(xfit,bfit);
```

bfit = 1.1235 1.5210 0.6582
3.2654 1.4832

Suppose that what we really care about is the area of the bump, and that the other parameters are “nuisance parameters”.

from Lecture 10: Maximum Likelihood parameter errors?

How accurately are the fitted parameters determined?

As Bayesians, we would **instead** say, what is their posterior distribution?

Taylor series:

$$-\frac{1}{2}\chi^2(\mathbf{b}) \approx -\frac{1}{2}\chi_{\min}^2 - \frac{1}{2}(\mathbf{b} - \mathbf{b}_0)^T \left[\frac{1}{2} \frac{\partial^2 \chi^2}{\partial \mathbf{b} \partial \mathbf{b}} \right] (\mathbf{b} - \mathbf{b}_0)$$

So, while exploring the χ^2 surface to find its minimum, we must also calculate the Hessian (2nd derivative) matrix at the minimum.

Then

$$P(\mathbf{b} | \{y_i\}) \propto \exp \left[-\frac{1}{2}(\mathbf{b} - \mathbf{b}_0)^T \Sigma_b^{-1} (\mathbf{b} - \mathbf{b}_0) \right] P(\mathbf{b})$$

with

$$\Sigma_b = \left[\frac{1}{2} \frac{\partial^2 \chi^2}{\partial \mathbf{b} \partial \mathbf{b}} \right]^{-1}$$

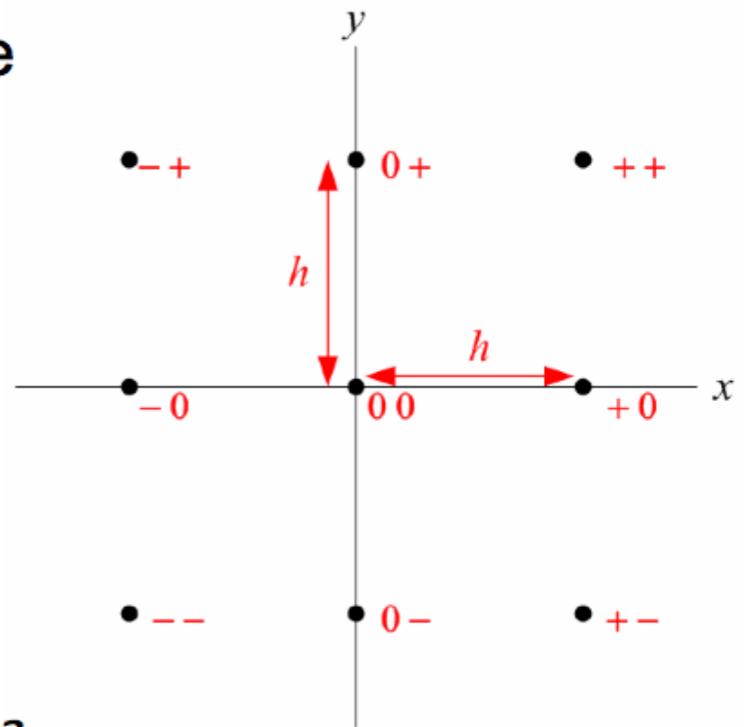

↑
covariance (or “standard error”) matrix
of the fitted parameters

Notice that if (i) the Taylor series converges rapidly and (ii) the prior is uniform, then the posterior distribution of the \mathbf{b} 's is multivariate Normal, a very useful CLT-ish result!

Maximum Likelihood parameter errors?

Numerical calculation of the Hessian by finite difference

$$\begin{aligned}\frac{\partial^2 f}{\partial x \partial y} &\approx \frac{1}{2h} \left(\frac{f_{++} - f_{-+}}{2h} - \frac{f_{+-} - f_{--}}{2h} \right) \\ &= \frac{1}{4h^2} (f_{++} + f_{--} - f_{+-} - f_{-+})\end{aligned}$$

bfit = 1.1235 1.5210 0.6582 3.2654 1.4832

```
chisqfun = @(b) sum(((ymodel(x,b)-y)./sig).^2)
h = 0.1;
unit = @(i) (1:5) == i;
hess = zeros(5,5);
for i=1:5, for j=1:5,
    bpp = bfit + h*(unit(i)+unit(j));
    bmm = bfit + h*(-unit(i)-unit(j));
    bpm = bfit + h*(unit(i)-unit(j));
    bmp = bfit + h*(-unit(i)+unit(j));
    hess(i,j) = (chisqfun(bpp)+chisqfun(bmm)...
                 -chisqfun(bpm)-chisqfun(bmp))./(2*h)^2;
end
end
covar = inv(0.5*hess)
```

This also works for the diagonal components. Can you see how?

Maximum Likelihood parameter errors?

For our example, $y(x|\mathbf{b}) = b_1 \exp(-b_2 x) + b_3 \exp\left(-\frac{1}{2} \frac{(x - b_4)^2}{b_5^2}\right)$

bfit =

1.1235	1.5210	0.6582	3.2654	1.4832
--------	--------	--------	--------	--------

hess =

64.3290	-38.3070	47.9973	-29.0683	46.0495
-38.3070	31.8759	-67.3453	29.7140	-40.5978
47.9973	-67.3453	723.8271	-47.5666	154.9772
-29.0683	29.7140	-47.5666	68.6956	-18.0945
46.0495	-40.5978	154.9772	-18.0945	89.2739

covar =

0.1349	0.2224	0.0068	-0.0309	0.0135
0.2224	0.6918	0.0052	-0.1598	0.1585
0.0068	0.0052	0.0049	0.0016	-0.0094
-0.0309	-0.1598	0.0016	0.0746	-0.0444
0.0135	0.1585	-0.0094	-0.0444	0.0948

This is the covariance structure of all the parameters, and indeed (at least in CLT normal approximation) gives their entire joint distribution!

The standard errors on each parameter separately are $\sigma_i = \sqrt{C_{ii}}$

sigs =

0.3672	0.8317	0.0700	0.2731	0.3079
--------	--------	--------	--------	--------

But why is this, and what about two or more parameters at a time (e.g. b_3 and b_5)?

multivariate normal distribution

Question: What is the generalization of

$$\chi^2 = \sum_i \left(\frac{x_i - \mu_i}{\sigma_i} \right)^2, \quad x_i \sim N(\mu_i, \sigma_i)$$

to the case where the x_i 's are normal, **but not independent?**

I.e., \mathbf{x} comes from a multivariate Normal distribution?

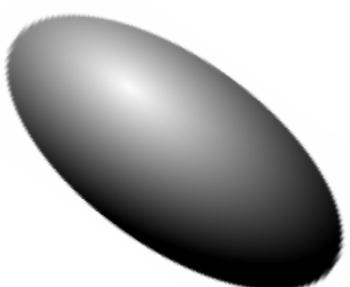

$$N(\mathbf{x}|\boldsymbol{\mu}, \boldsymbol{\Sigma}) = \frac{1}{(2\pi)^{M/2} \det(\boldsymbol{\Sigma})^{1/2}} \exp[-\frac{1}{2}(\mathbf{x} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu})]$$

The mean and covariance of r.v.'s from this distribution **are***

$$\boldsymbol{\mu} = \langle \mathbf{x} \rangle \quad \boldsymbol{\Sigma} = \langle (\mathbf{x} - \boldsymbol{\mu})(\mathbf{x} - \boldsymbol{\mu})^T \rangle$$

In the one-dimensional case σ is the standard deviation, which can be visualized as “error bars” around the mean.

In more than one dimension $\boldsymbol{\Sigma}$ can be visualized as an error ellipsoid around the mean in a similar way.

$$1 = (\mathbf{x} - \boldsymbol{\mu})^T \boldsymbol{\Sigma}^{-1} (\mathbf{x} - \boldsymbol{\mu})$$

linear error propagation for arbitrary function of parameters

What is the uncertainty in quantities other than the fitted coefficients:

Method 1: Linearized propagation of errors

\mathbf{b}_0 is the MLE parameters estimate

$\mathbf{b}_1 \equiv \mathbf{b} - \mathbf{b}_0$ is the RV as the parameters fluctuate

$$f \equiv f(\mathbf{b}) = f(\mathbf{b}_0) + \nabla f \mathbf{b}_1 + \dots$$

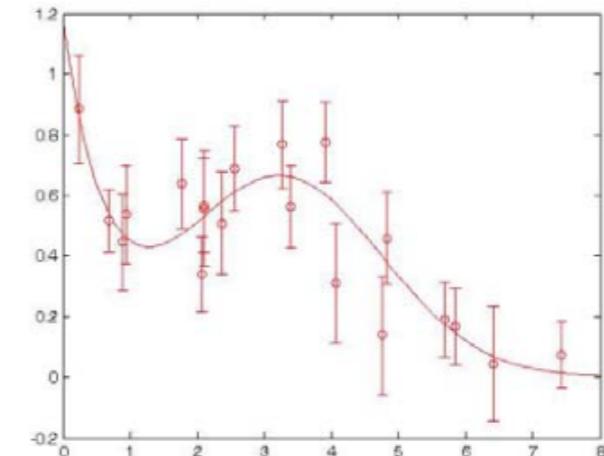

$$\langle f \rangle \approx \langle f(\mathbf{b}_0) \rangle + \nabla f \cancel{\langle \mathbf{b}_1 \rangle} = f(\mathbf{b}_0)$$

$$\begin{aligned}\langle f^2 \rangle - \langle f \rangle^2 &\approx 2f(\mathbf{b}_0)(\nabla f \cancel{\langle \mathbf{b}_1 \rangle}) + \langle (\nabla f \mathbf{b}_1)^2 \rangle \\ &= \nabla f \langle \mathbf{b}_1 \mathbf{b}_1^T \rangle \nabla f^T \\ &= \nabla f \Sigma \nabla f^T\end{aligned}$$

linear error propagation for arbitrary function of parameters

In our example, if we are interested in the area of the “hump”,

```
bfit =  
    1.1235   1.5210   0.6582   3.2654   1.4832  
covar =  
    0.1349   0.2224   0.0068  -0.0309   0.0135  
    0.2224   0.6918   0.0052  -0.1598   0.1585  
    0.0068   0.0052   0.0049   0.0016  -0.0094  
   -0.0309  -0.1598   0.0016   0.0746  -0.0444  
    0.0135   0.1585  -0.0094  -0.0444   0.0948
```

$$f = b_3 b_5$$

$$\nabla f = (0, 0, b_5, 0, b_3)$$

$$\nabla f \Sigma \nabla f^T = b_5^2 \Sigma_{33} + 2b_3 b_5 \Sigma_{35} + b_3^2 \Sigma_{55} = 0.0336$$

$$\sqrt{0.0336} = 0.18$$

$$\text{So } b_3 b_5 = 0.98 \pm 0.18 \quad \leftarrow \text{the one standard deviation (1-}\sigma\text{) error bar}$$

A function of normals is not normal

Sampling the posterior histogram

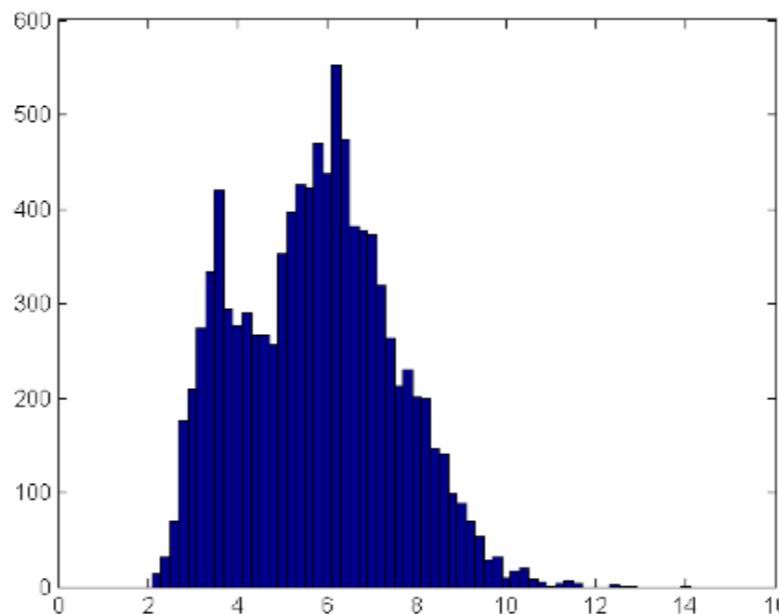

Method 2: Sample from the posterior distribution

1. Generate a large number of (vector) \mathbf{b} 's

$$\mathbf{b} \sim \text{MVNormal}(\mathbf{b}_0, \Sigma_b)$$

2. Compute your $f(\mathbf{b})$ separately for each \mathbf{b}

3. Histogram

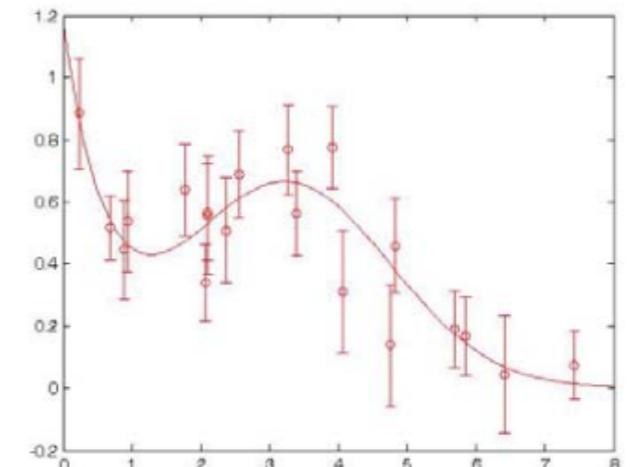

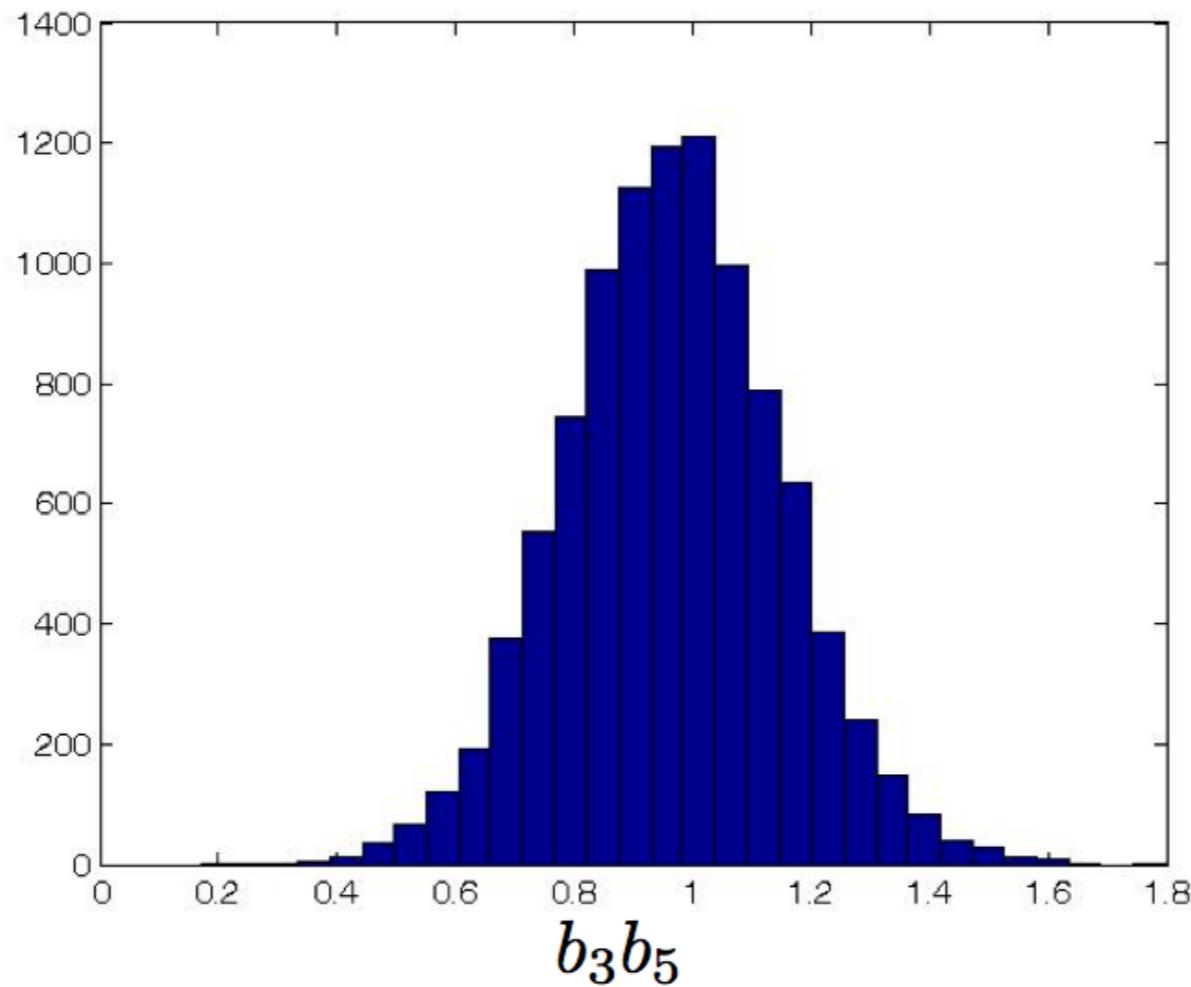

Note again that \mathbf{b} is typically (close to) m.v. normal because of the CLT, but your (nonlinear) f may not, in general, be anything even close to normal!

Sampling the posterior histogram

Our example:

```
bees = mvnrnd(bfit,covar,10000);  
humps = bees(:,3).*bees(:,5);  
hist(humps,30);  
std(humps)
```

std = 0.1833

Does it matter that I use the full covar, not just the 2x2 piece for parameters 3 and 5?

χ^2 distribution goodness of fit

we have **assumed** that, for **some** value of the parameters \mathbf{b}
the model $y(\mathbf{x}_i|\mathbf{b})$ is correct

Suppose that the model $y(\mathbf{x}_i|\mathbf{b})$ does fit. This is the **null hypothesis**.

Then the “statistic” $\chi^2 = \sum_{i=1}^N \left(\frac{y_i - y(\mathbf{x}_i|\mathbf{b})}{\sigma_i} \right)^2$ is the sum of N t²-values.

(not quite)

So, if we imagine repeated experiments (which Bayesians refuse to do),
the statistic should be distributed as Chisquare(N).

If our experiment is very unlikely to be from this distribution, we
consider the model to be disproved. In other words, it is a p-value
test.

χ^2 distribution (from Lecture 10)

$$p_X(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}x^2} \Rightarrow x \sim N(0, 1)$$

$$y = x^2$$

$$p_Y(y) dy = 2p_X(x) dx$$

$$p_Y(y) = y^{-1/2} p_X(y^{1/2}) = \frac{1}{\sqrt{2\pi y}} e^{-\frac{1}{2}y}$$

χ^2 is a “statistic” defined as the sum of the squares of n independent t-values.

$$\chi^2 = \sum_i \left(\frac{x_i - \mu_i}{\sigma_i} \right)^2, \quad x_i \sim N(\mu_i, \sigma_i)$$

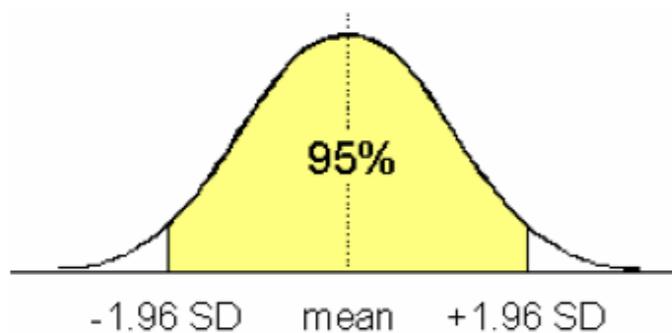

Chisquare(ν) is a distribution (special case of Gamma), defined as

$$\chi^2 \sim \text{Chisquare}(\nu), \quad \nu > 0$$

$$p(\chi^2) d\chi^2 = \frac{1}{2^{\frac{1}{2}\nu} \Gamma(\frac{1}{2}\nu)} (\chi^2)^{\frac{1}{2}\nu-1} \exp(-\frac{1}{2}\chi^2) d\chi^2, \quad \chi^2 > 0$$

confidence intervals

The variances of *one parameter* at a time imply confidence intervals as for an ordinary 1-dimensional normal distribution:

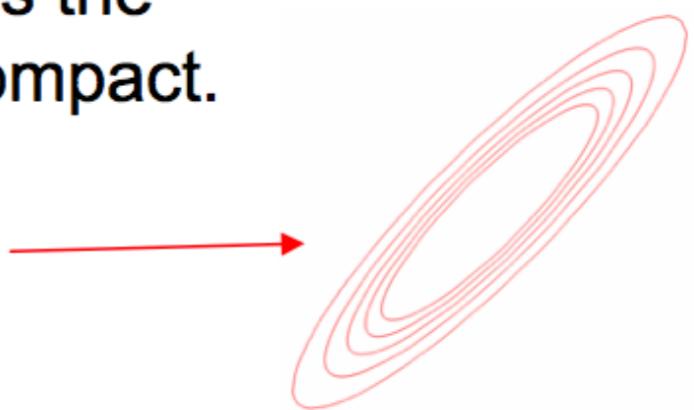

(Remember to take the square root of the variances to get the standard deviations!)

If you want to give confidence regions for *more than one parameter* at a time, you have to decide on a shape, since any shape containing 95% (or whatever) of the probability is a 95% confidence region!

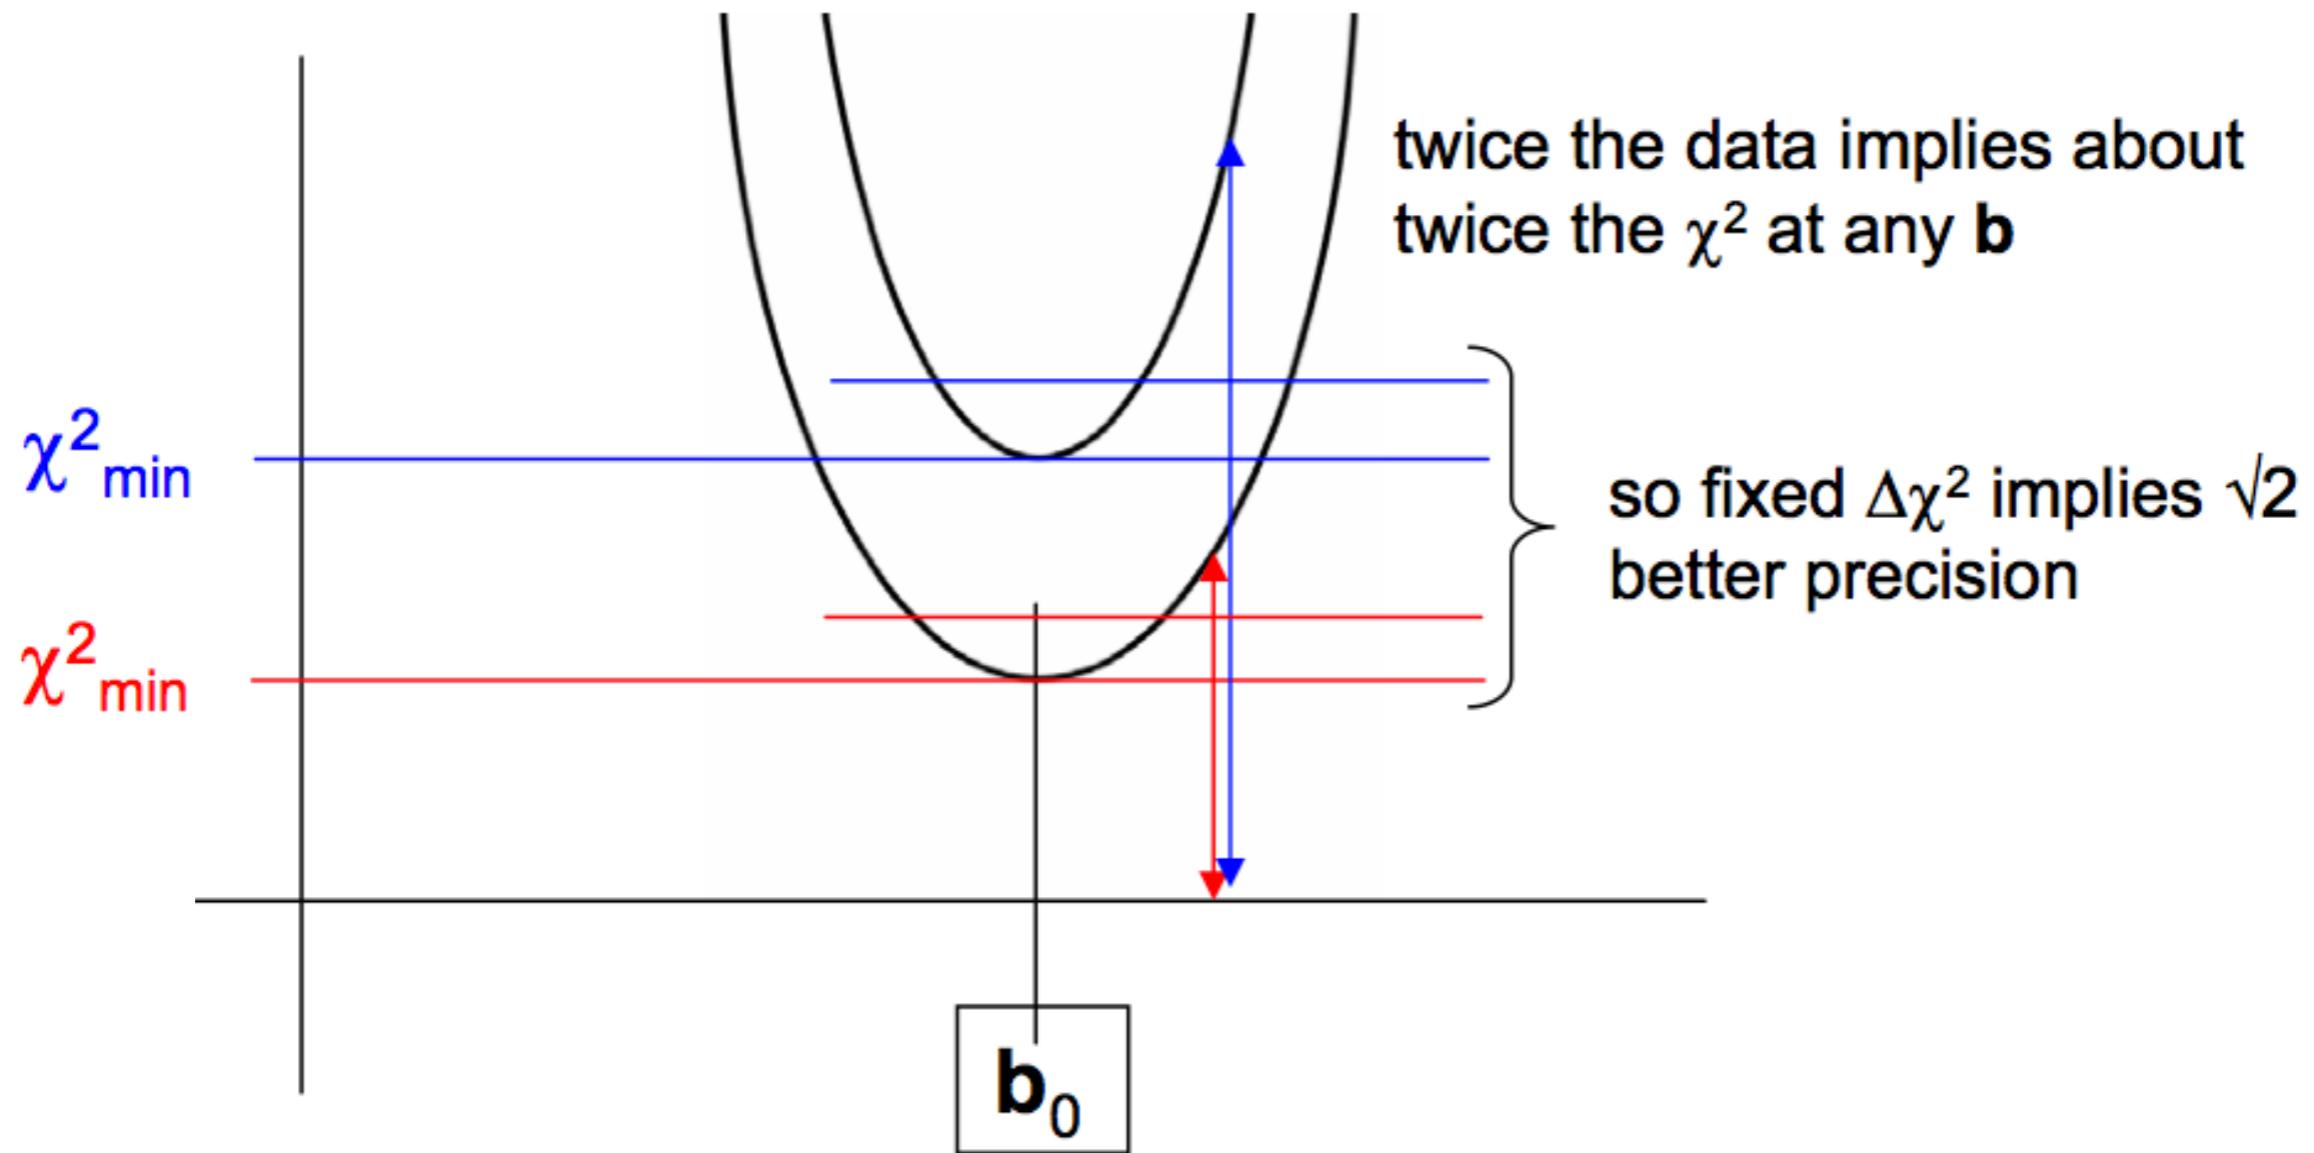

It is *conventional* to use contours of probability density as the shapes (= contours of $\Delta\chi^2$) since these are maximally compact.

But **which** $\Delta\chi^2$ contour contains 95% of the probability?

χ^2 distribution

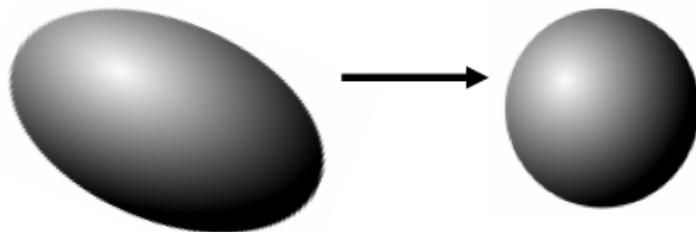

Measurement precision improves with the amount of data N as $N^{-1/2}$

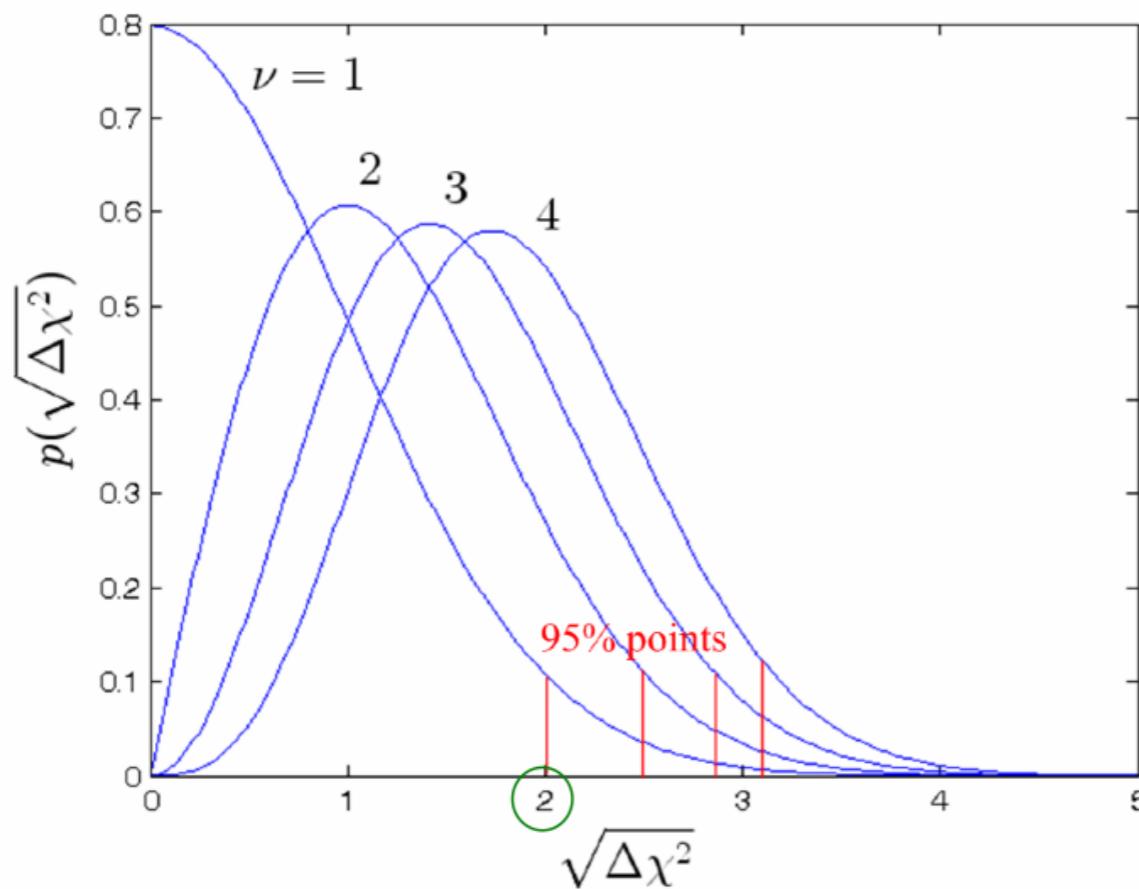

confidence intervals

What $\Delta\chi^2$ contour in v dimensions contains some percentile probability?

Rotate and scale the covariance to make it spherical.
(Linear, so contours still contain same probability.)

Now, each dimension is an independent Normal, and contours are labeled by radius squared (sum of v individual t^2 values), so $\Delta\chi^2 \sim \text{Chisquare}(v)$

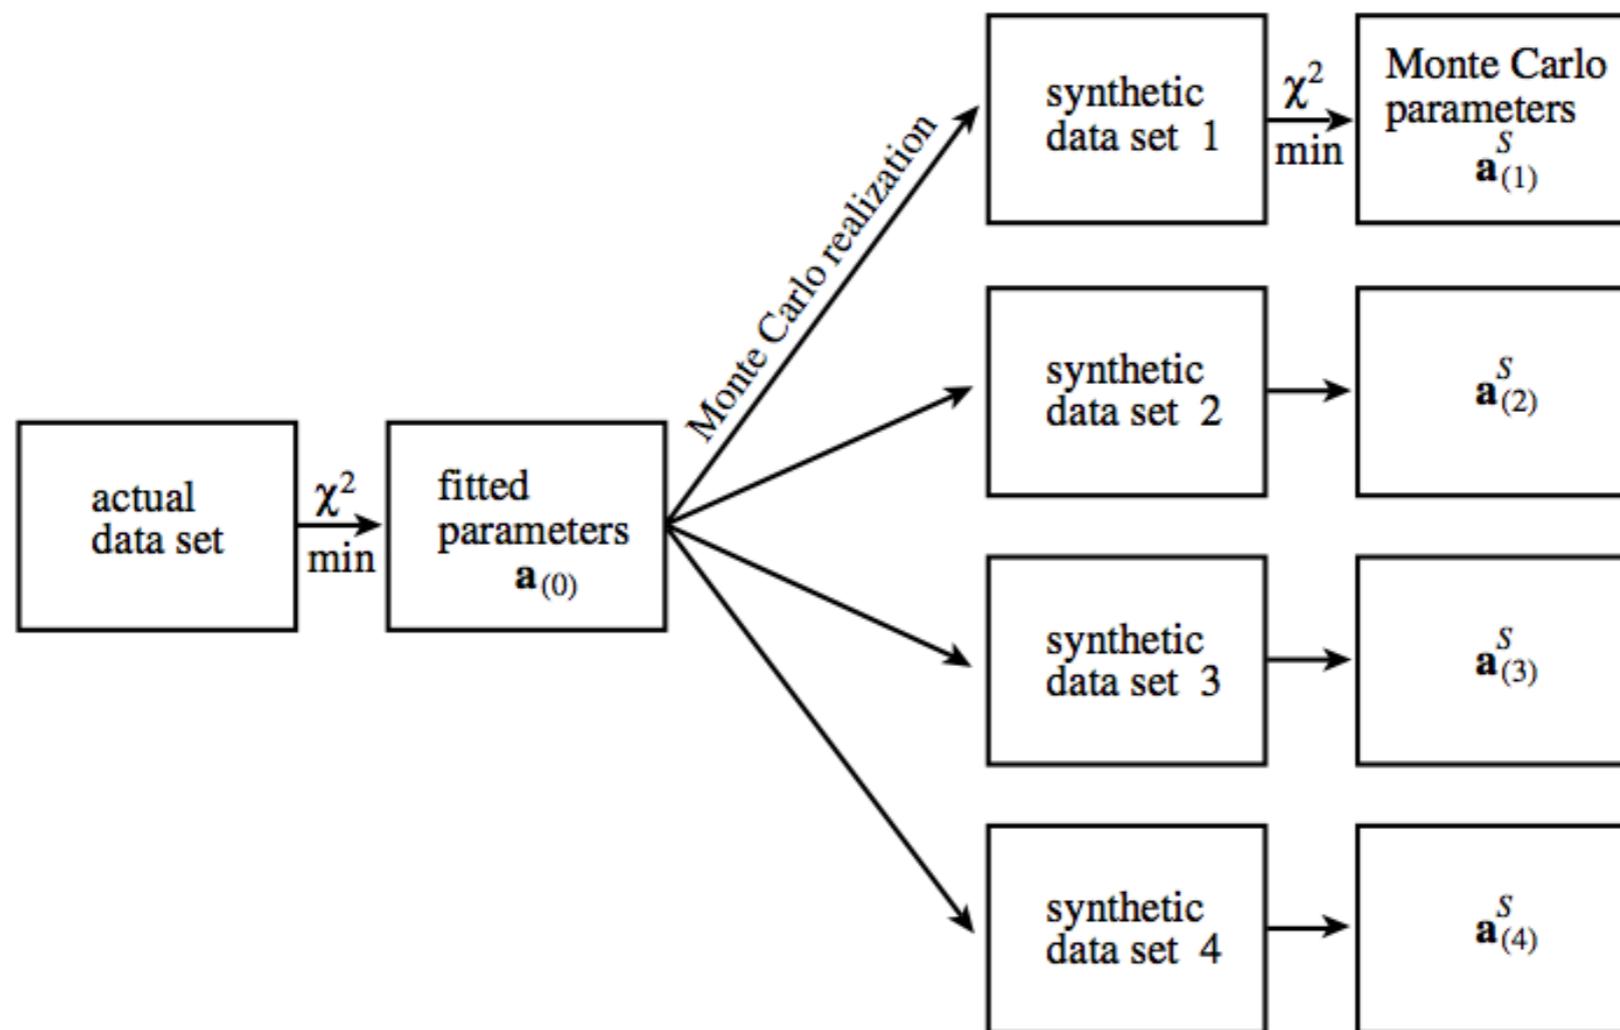

$\Delta\chi^2$ as a Function of Confidence Level p and Number of Parameters of Interest v						
p	v					
	1	2	3	4	5	6
68.27%	1.00	2.30	3.53	4.72	5.89	7.04
90%	2.71	4.61	6.25	7.78	9.24	10.6
95.45%	4.00	6.18	8.02	9.72	11.3	12.8
99%	6.63	9.21	11.3	13.3	15.1	16.8
99.73%	9.00	11.8	14.2	16.3	18.2	20.1
99.99%	15.1	18.4	21.1	23.5	25.7	27.9

You sometimes learn “facts” like: “delta chi-square of 1 is the 68% confidence level”. We now see that this is true only for one parameter at a time.

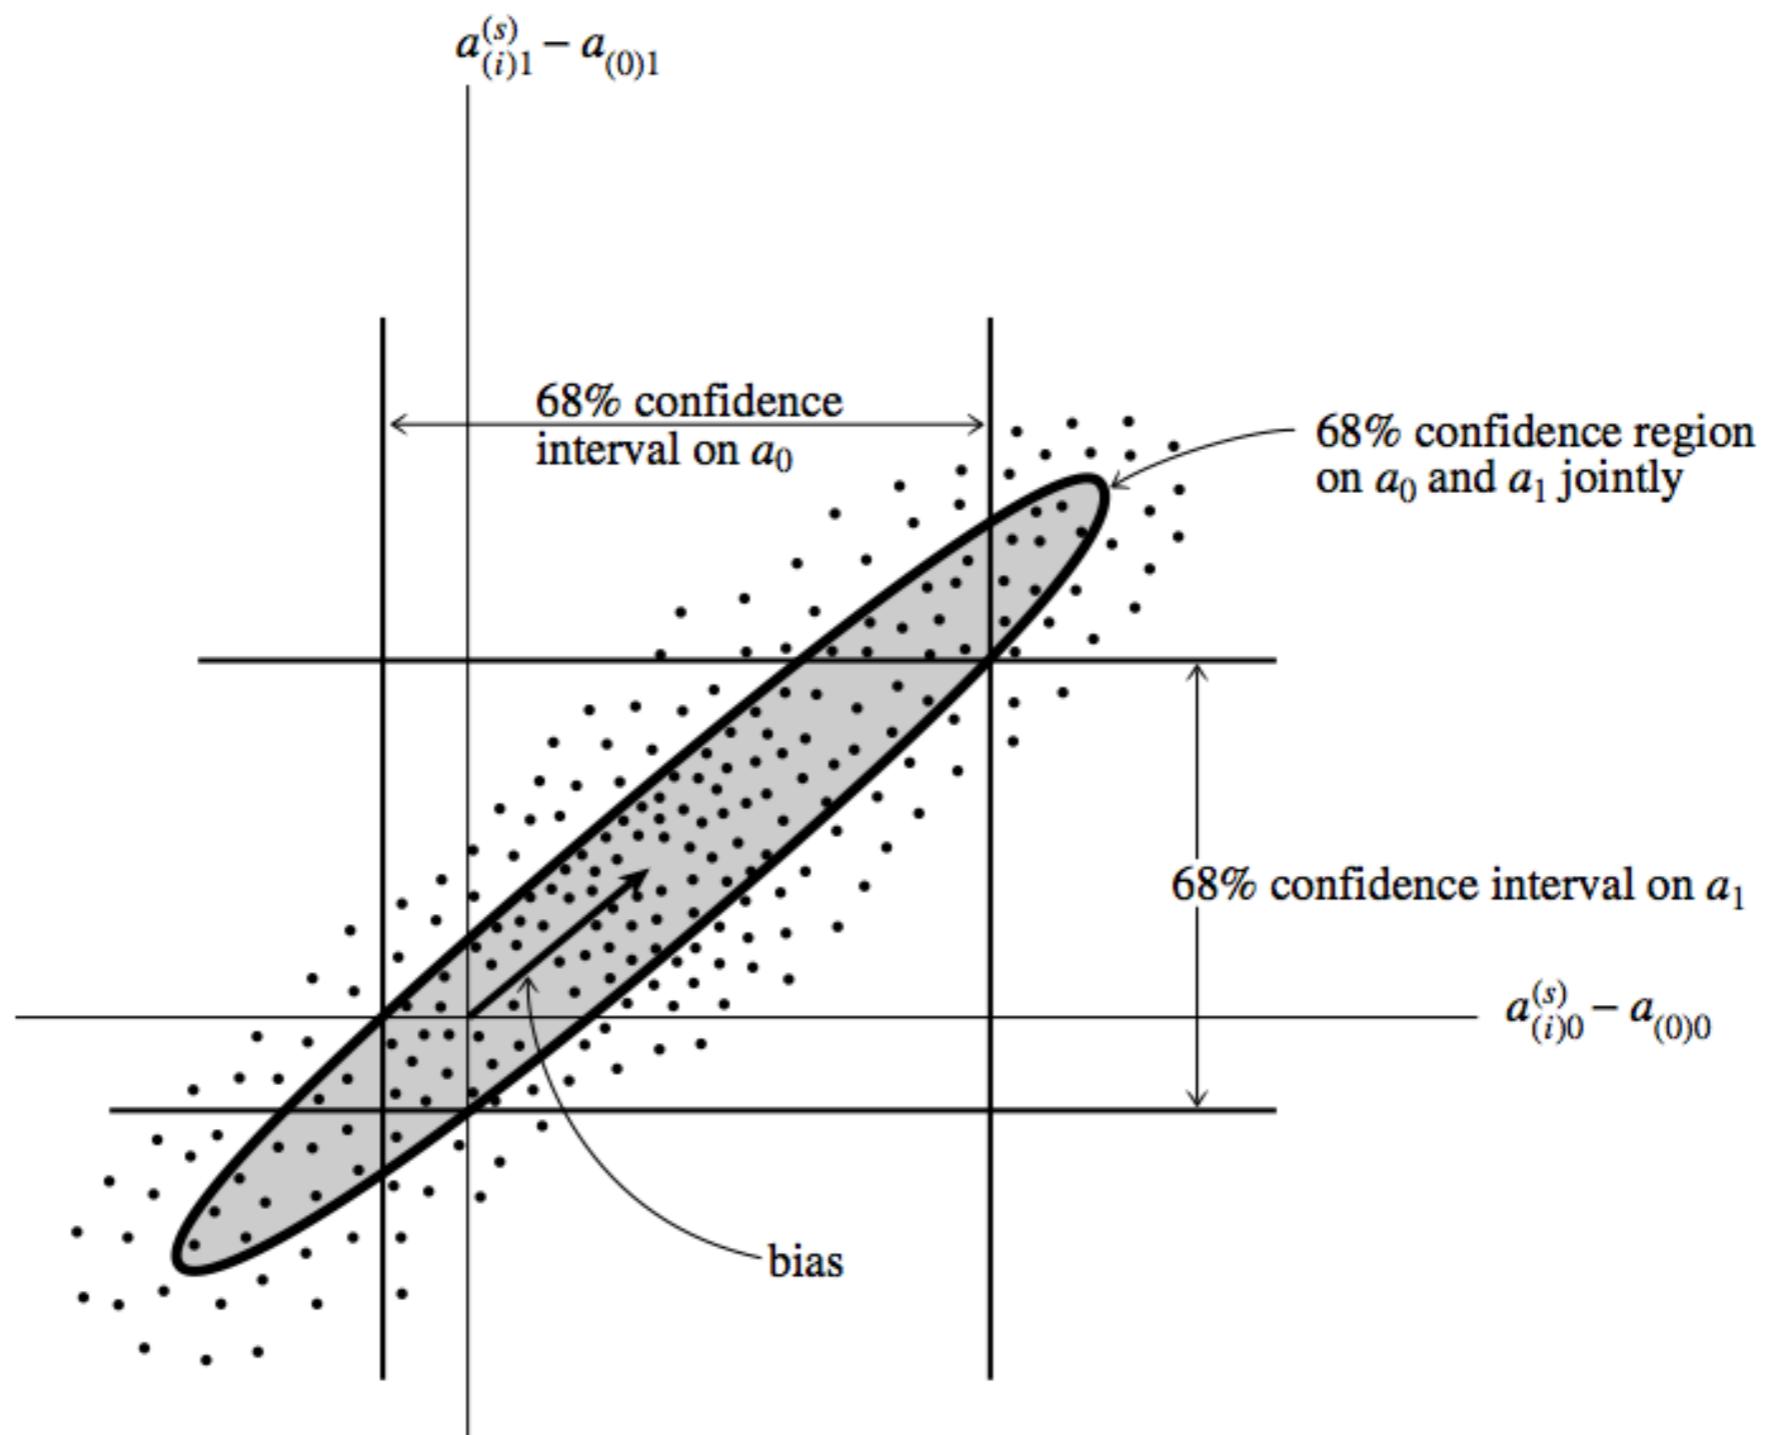

confidence intervals

Monte Carlo to generate parameters (non-linear models):

confidence intervals

Monte Carlo distribution of the non-linear parameters:

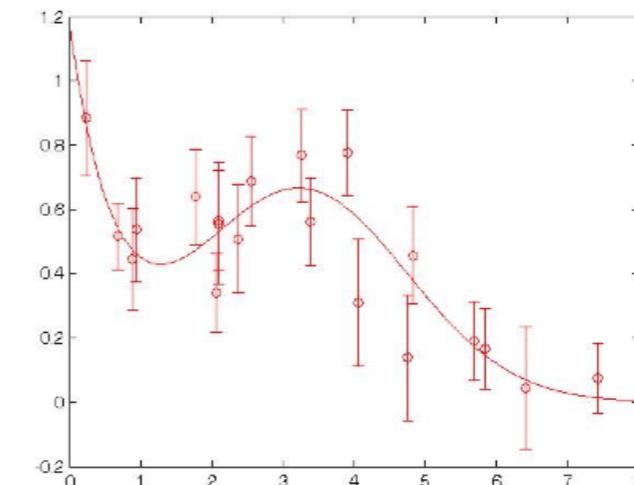

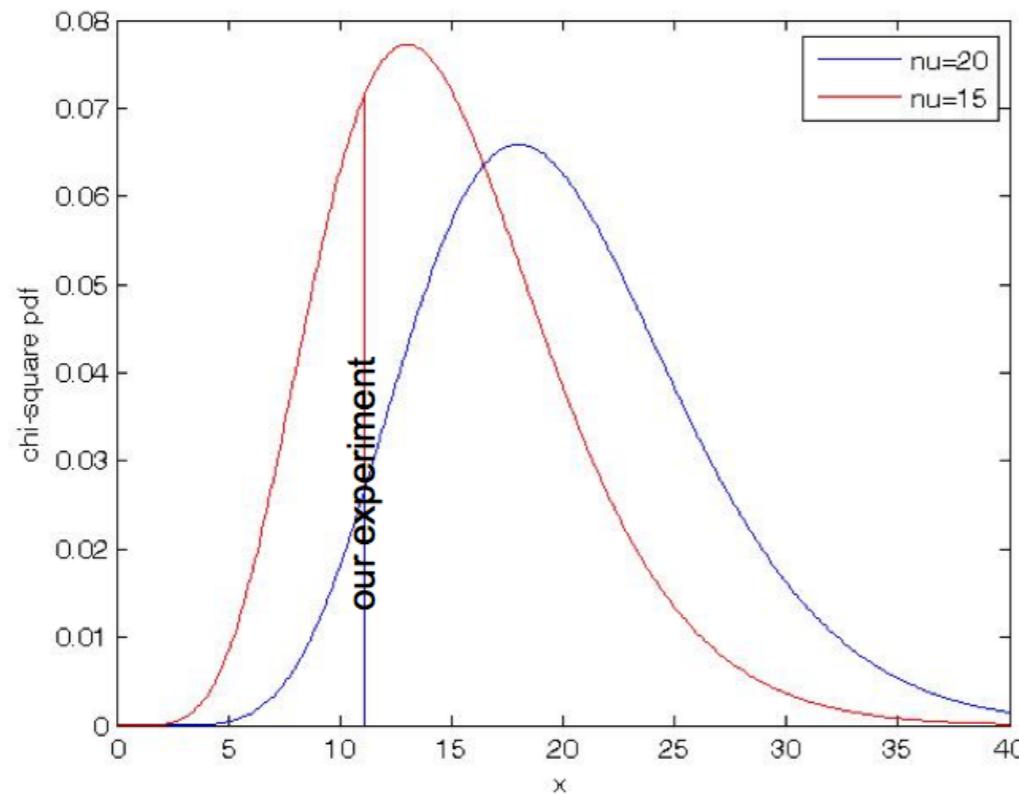

what is the Degree of Freedom?

How is our fit by this test?

In our example, $\chi^2(\mathbf{b}_0) = 11.13$

This is a bit unlikely in Chisquare(20),
with (left tail) $p=0.0569$.

In fact, if you had many repetitions of the experiment, you would find that
their χ^2 is not distributed as Chisquare(20), but rather as Chisquare(15)!
Why?

the magic word is:
“degrees of freedom” or DOF

what is the Degree of Freedom?

Degrees of Freedom: Why is χ^2 with N data points “not quite” the sum of N t^2 -values? Because DOFs are reduced by constraints.

First consider a hypothetical situation where the data has linear constraints:

joint distribution on all the t's, if they are independent

$$t_i = \frac{y_i - \mu_i}{\sigma_i} \sim N(0, 1)$$
$$p(\mathbf{t}) = \prod_i p(t_i) \propto \exp\left(-\frac{1}{2} \sum_i t_i^2\right)$$

χ^2 is squared distance from origin $\sum t_i^2$

Linear constraint:

$$\sum_i \alpha_i y_i = C = \langle C \rangle = \sum_i \alpha_i \mu_i$$

$$C = \sum_i \alpha_i (\sigma_i t_i + \mu_i)$$

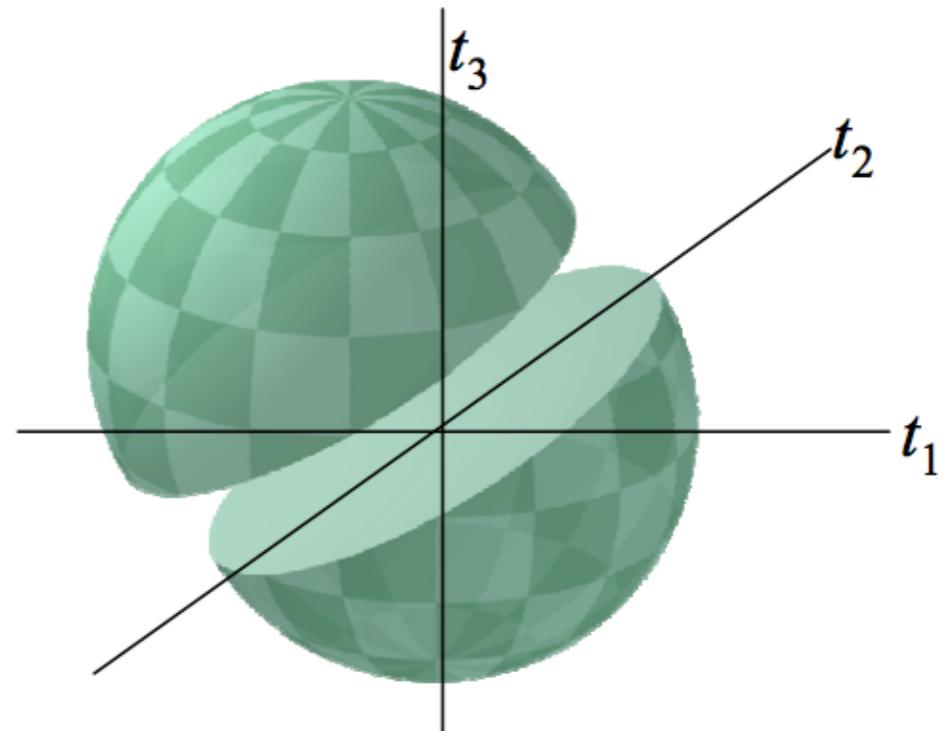

$$= \sum_i \alpha_i \sigma_i t_i + C$$

$$\text{So, } \sum_i \alpha_i \sigma_i t_i = 0$$

a hyper plane through the origin in t space!

what is the Degree of Freedom?

Constraint is a plane cut through the origin. Any cut through the origin of a sphere is a circle.

So the distribution of distance from origin is the same as a multivariate normal “ball” in the lower number of dimensions. Thus, each linear constraint reduces ν by exactly 1.

We don't have explicit constraints on the y_i 's. But as the y_i 's wiggle around (within their errors) we do have the constraint that we want to keep the MLE estimate \mathbf{b}_0 fixed. (E.g., we have 20 wiggling y_i 's and only 5 b_i 's to keep fixed.)

So by the implicit function theorem, there are M (number of parameters) approximately linear constraints on the y_i 's. So $\nu = N - M$, the so-called number of degrees of freedom (d.o.f.).

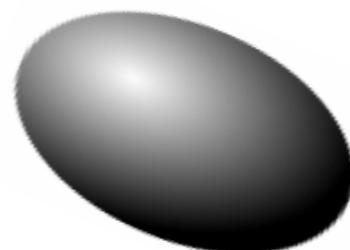

what is the Degree of Freedom?

Review:

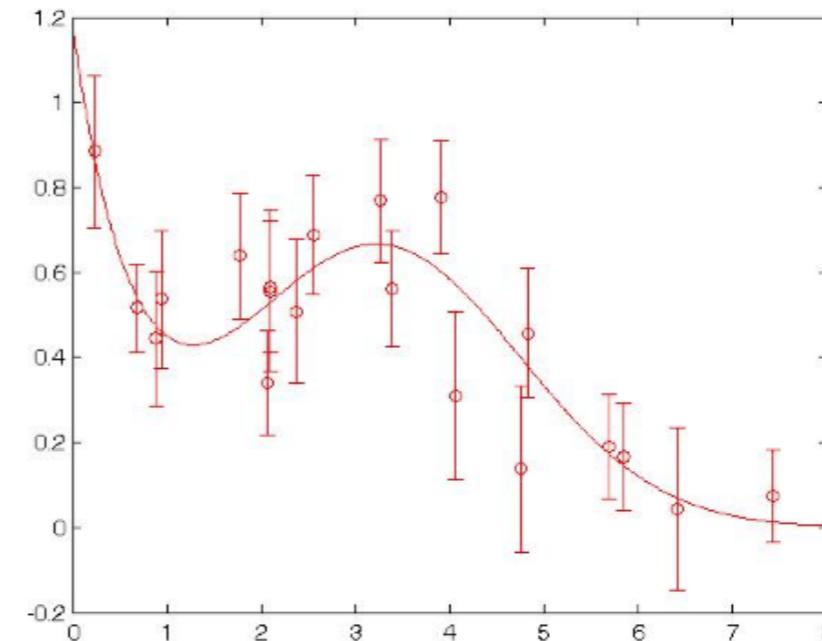

1. Fit for parameters by minimizing

$$\chi^2 = \sum_{i=1}^N \left(\frac{y_i - y(\mathbf{x}_i | \mathbf{b})}{\sigma_i} \right)^2$$

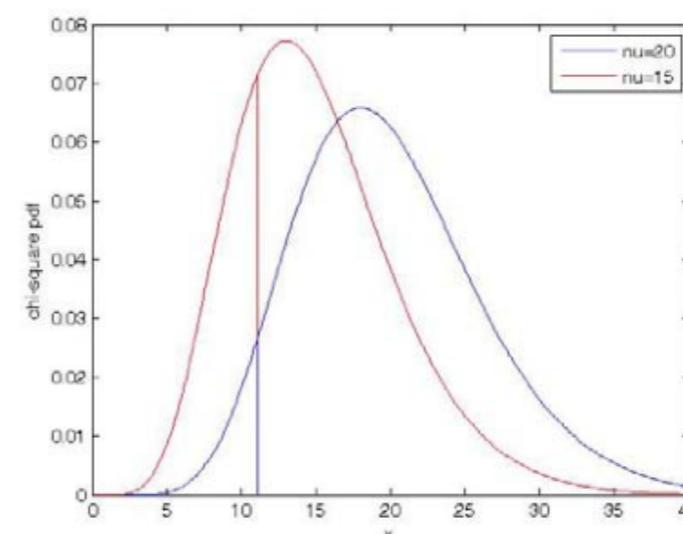

2. (Co)variances of parameters, or confidence regions, by the change in χ^2 (i.e., $\Delta\chi^2$) from its minimum value χ^2_{\min} .

3. Goodness-of-fit (accept or reject model) by the p-value of χ^2_{\min} using the correct number of DOF.

		$\Delta\chi^2$ as a Function of Confidence Level p and Number of Parameters of Interest v					
		1	2	3	4	5	6
p	1	1.00	2.30	3.53	4.72	5.89	7.04
	90%	2.71	4.61	6.25	7.78	9.24	10.6
	95.45%	4.00	6.18	8.02	9.72	11.3	12.8
	99%	6.63	9.21	11.3	13.3	15.1	16.8
	99.73%	9.00	11.8	14.2	16.3	18.2	20.1
	99.99%	15.1	18.4	21.1	23.5	25.7	27.9

Goodness-of-fit

Goodness-of-fit with $\nu = N - M$ degrees of freedom:

we expect $\chi^2_{\min} \approx \nu \pm \sqrt{2\nu}$

this is an RV over the population of different data sets (a frequentist concept allowing a p-value)

Confidence intervals for parameters \mathbf{b} :

we expect $\chi^2 \approx \chi^2_{\min} \pm O(1)$

this is an RV over the population of possible model parameters for a single data set, a concept shared by Bayesians and frequentists

How can $\pm O(1)$ be significant when the uncertainty is $\pm \sqrt{2\nu}$?

Answer: Once you have a particular data set, there is no uncertainty about what its χ^2_{\min} is. Let's see how this works out in scaling with N :

χ^2 increases linearly with $\nu = N - M$

$\Delta\chi^2$ increases as N (number of terms in sum), but also decreases as $(N^{-1/2})^2$, since \mathbf{b} becomes more accurate with increasing N :

$$\Delta\chi^2 \propto N(\delta b)^2, \quad \delta b \propto N^{-1/2} \quad \Rightarrow \quad \Delta\chi^2 \propto \text{const}$$

quadratic, because at minimum

universal rule of thumb
